

Turkey Earthquakes (1915-2021)

Elanur Lenger
 elanurlenger@ogr.eskisehir.edu.tr

This plot shows that the vast majority of earthquakes in Turkey occur at shallow depths between 0-50 km. While frequency decreases with depth, the concentration of events near the surface provides numerical evidence that shallow earthquakes pose the highest risk to residential areas.

This chart proves that earthquakes in Turkey are not distributed homogeneously, with major concentrations in the Mediterranean, Aegean, and around Van. This significant clustering along the western coasts provides numerical evidence for prioritizing resource allocation in disaster logistics.

This time series graph illustrates the rising trend in recorded earthquakes since the 1970s due to technological advances, reaching record peaks like 934 in the 2000s. For our data visualization project, this trend proves high seismic uncertainty in Turkey, emphasizing that disaster logistics plans must always be prepared for worst-case scenarios and sudden spikes.

This density map highlights earthquake clustering and hotspots along Türkiye's fault lines. Proving that seismic risk is not distributed homogeneously, it provides numerical evidence for prioritizing resource allocation in disaster management.

This chart compares the 7 geographical regions of Turkey based on their historical maximum earthquake magnitudes. Central Anatolia, Aegean, and Eastern Anatolia stand out as the highest-risk regions in terms of peak magnitude potential. The variance between average and maximum intensities provides numerical evidence for defining region-specific 'resilience levels' in disaster management models.
